Overview

The Morningstar Portfolio Risk Score assesses risk and diversification to help investors, financial professionals, and those who oversee large groups of financial professionals to assess whether the riskiness of the portfolio matches the risk profile of an investor. It has optimal value when combined with the Morningstar Risk Profiler and the personalized Risk Comfort Range of an investor. The Portfolio Risk Score enables investors to be matched with suitable portfolios that align with their respective risk profile.

At the heart of the system is a risk-scoring engine that is capable of automatically analyzing millions of portfolios and assigning a numeric risk score in which diversified asset-allocation portfolios typically receive a score ranging from 0 to 80 and highly concentrated portfolios and asset-class-specific portfolios (such as a small-growth fund, a sector fund, or a country-specific fund) will typically receive scores between 80 and 100. Scores above 100 indicate that portfolios are elevated to extreme levels of risk and are probably not suitable to represent a complete investor portfolio. The score is based on the portfolio's relationship to an extended risk spectrum based on the Morningstar Target Allocation Index family.

The indexes of the Morningstar® Target Allocation Index family, or MTAI, provide consistent measures of risk by asset-class exposures to Morningstar building block indexes and are aligned with the Morningstar Category classifications for asset-allocation funds. The underlying index weights are derived from eligible open-end funds in Morningstar's fund holdings data and therefore reflect the collective wisdom of the numerous asset managers producing asset-allocation funds in the relevant categories. While one cannot invest directly in the Morningstar Target Allocation Index family, we believe the asset allocations embedded in these indexes represent appropriate asset-allocation portfolios for a wide variety of investors.

While no system can guarantee portfolio quality nor ensure against losses, MPRS can serve as an additional due-diligence tool for investors, financial professionals, compliance officers monitoring a large number of portfolios (or funds), and for regulators. The Morningstar Risk Ecosystem is depicted in Exhibit 1.

Exhibit 1 Morningstar Risk Profiler and Portfolio Risk Scoring System – The Advice Flow

Source: Morningstar.

This document explains the methodology behind the Portfolio Risk Score (the right panel of Exhibit 1) and demonstrates its application.

Return Volatility-Based Risk Scores

The Portfolio Risk Scores are calculated based on the estimated volatility of fund returns. The volatility estimates are mostly generated by the Morningstar Risk Model's holdings-based style analysis and supplemented by Sharpe's return-based style analysis for portfolios with insufficient holdings data. Volatility is widely understood as a measure of risk. Exhibits 5 and 6 in Appendix A show that the risk is higher for funds with style tilts and for funds with higher equity weights in the allocation.

Another popular approach of measuring the level of risk in a portfolio is by how many growth assets, typically equities, are in the portfolio. For example, a 60/40 equity/fixed-income portfolio is typically classified as moderate and an 80/20 portfolio as aggressive. This approach excels in its simplicity and interpretability but requires the classification of asset classes. Moreover, the percentage of growth asset allocation may not accurately capture the risk of the portfolio. Exhibit 7 in Appendix A shows that the volatility of the S&P 500 in 2022 is almost twice the volatility in 2017, indicating that the same allocation to growth assets can have vastly different risk levels depending on the market.

Unlike the asset-allocation-based approach, a volatility-based scoring approach is not prone to ambiguous classification of growth assets, especially in the market where new strategies are becoming more diverse and far from the traditional equity and fixed-income allocation. A volatility-based risk scoring approach can incorporate nontraditional investment types that do not fall neatly into an asset-allocation approach. A potential concern of a volatility-based scoring system is the stability of the score of a fund that could vary significantly on the market volatility condition.

To ensure the stability of volatility-based scores while retaining the benefits of the asset-allocation-based approach, the Portfolio Risk Score scores a portfolio based its volatility relative to that of a set of asset-allocation indexes. The asset-allocation indexes work as anchor points that measure the overall market condition and allow us to retain the connection to the traditional allocation views and risk classification. We choose Morningstar Target Allocation Indexes and explain the specific score calculation in the following sections.

Morningstar® Target Allocation Indexes

For each family of target allocation categories, Morningstar creates a corresponding family of multi-asset-class indexes, the Morningstar Target Allocation Indexes. Each year, Morningstar calculates the sub-asset-class weights from the average weights of the funds in the category. Exhibit 2 presents the equity/fixed-income split of the seven target allocation categories in the U.S. market. The two right-most categories were extended from the Aggressive TAI to represent the high-risk and extreme-risk portfolios by uniformly increasing all the equity allocations to make them 110% and 140%, setting all the bond allocations to 0%, and setting the cash allocation to negative 10% and negative 40%, respectively.

Exhibit 2 Morningstar U.S. Target Asset Allocation Indexes

Asset Class	Conservative	Moderate Conservative	Moderate	Moderate Aggressive	Aggressive	Aggressive Extension 1	Aggressive Extension 2
US Equity	16.5%	28.5%	47.0%	55.0%	68.5%	81.5%	103.7%
DM xUS Equity	5.0%	9.5%	10.5%	18.0%	19.5%	23.2%	29.5%
EM Equity	1.0%	2.0%	2.5%	4.5%	4.5%	5.4%	6.8%
US Core Bond	58.5%	45.0%	30.5%	15.5%	4.0%	0.0%	0.0%
Global Core Bond ex US	11.5%	9.5%	4.5%	2.5%	0.5%	0.0%	0.0%
Cash	7.5%	5.5%	5.0%	4.5%	3.0%	-10.0%	-40.0%

Source: Morningstar.

To ensure that the risk scores are stable over time and not clustered around the 15% to 20% volatility range, the risk scores are anchored to the risk bands using the long-term risk profiles of the Morningstar Target Allocation Indexes as shown in Exhibit 3. The risk bands then facilitate the interpretation of risk scores so that the portfolio is gauged against the risk comfort range and evaluate whether the portfolio is appropriate for the investors. Out of six regional TAIs, U.S. TAIs were chosen as a reference point to anchor the risk scores and define the mapping between volatility ranges and risk bands. In other words, the risk scores are calculated relative to the U.S. market.

Identify Modeling Approach

The Morningstar Portfolio Risk Score uses a consistent methodology to translate a portfolio's level of risk into an overall score. To determine the portfolio's risk estimate, the Portfolio Risk Score system uses a hybrid approach combining a holdings-based methodology from Morningstar's Risk Model and a returns-based methodology using a return-based style analysis approach. Between these two approaches, we can cover virtually the entire managed product, stock, and fixed-income universes and client portfolios. Depending on the information we have about a portfolio, we will select the optimal methodology to use, with preference giving to the holdings-based methodology.

Identifying a Portfolio

The process for calculating a Portfolio Risk Score begins by identifying the investments—mutual funds, exchange-traded funds, individual securities, and so on—in the portfolio. When deployed for home office analytics and monitoring, portfolios are typically identified using information from the Morningstar system or a template using Morningstar's unique security identification system. When deployed for direct use by a financial professional (or an individual investor), these users can leverage existing client portfolios or model portfolios or upload them using an import feature. Alternatively, they can analyze portfolios on the fly by entering portfolio positions.

The Portfolio Risk Score can also be calculated for stocks, fixed-income securities, and managed investment products such as open-end mutual funds, exchange-traded funds, collective investment trusts, unit investment trusts, separately managed accounts, variable-annuity/variable-life subaccounts, segregated funds, and pooled funds.

The automated analysis of a portfolio is dependent on Morningstar having at least 80% portfolio holdings coverage identified through Morningstar's Risk Model or 24 months (preferably 48 months) of trailing returns for the current constituents (mutual funds, ETFs, individual securities, and so on) of a portfolio. In general, for a portfolio to receive a Morningstar Portfolio Risk Score, the scoring engine requires Security IDs for 100% of the portfolio.

There are checks in place to determine whether the portfolio to be scored contains a sufficient returns history or holdings data. If insufficient data exist, we would not be confident in the score and would not score the portfolio/fund in question.

For funds or ETFs, the process is to score anything with more than 80% holdings coverage identified through the Morningstar Risk Model and, for ones without sufficient holdings data, at least 24 months of return history and utilize proxy data based on the category average returns to fill in missing return history up to the required 48 months. For individual securities, the security is covered via the holdings-based approach provided it falls within the Risk Model coverage universe. No return history is required in these cases.

For a client (bespoke) portfolio, we use a special process to determine whether to score the portfolio and the approach for risk estimate. Since there may be many constituents in a client portfolio, we need to examine our coverage of the constituents to determine whether to score or not. The client portfolio will be scored by the holdings-based approach if the weighted sum of the holdings-coverage weights is at least 80%. Upon insufficient holdings data, the returns-based approach will be invoked.

For a returns-based approach, we multiply the weight of each constituent in the portfolio by the number of actual months of return history it has. The portfolio will be scored if the weighted sum meets or exceeds 24 months and not scored if it is less than 24 months. For portfolios that will be scored, the constituents that are missing return history will use proxy data based on the category average for each constituent to the extent that their individual returns history is less than 48 months. The constituents' return histories are then rolled up into a composite return history for the portfolio for 48 months, which is the return history ultimately used for the subsequent analysis.

Some examples of what this might mean for a bespoke portfolio are:

- ▶ A custom portfolio with five constituents and holdings-based coverage weight at 92% will be scored based on risk estimate using the Risk Model.
- ▶ A custom portfolio with five constituents and holdings-based coverage weight at 70% will not be scored based on risk estimate using the Risk Model. Next, our system will test whether the portfolio can be scored using a returns-based approach.
- ▶ Assuming not scored by the holdings-based approach using the Risk Model, a custom portfolio with five constituents where each constituent has exactly 24 months of return history would have the remaining history proxied based on category averages for each of the constituents and would be scored. Assuming not scored by the holdings-based approach using the Risk Model, a custom portfolio with 50% of the portfolio held in one holding with a full 48 months of return history and other constituents with one month of history would be scored. The constituents with one month of returns would have 47 months of return history based on their respective category averages.

Estimate Volatility of Portfolio Returns

The risk score engine takes the volatility estimate and translates it into the risk score. The first step to calculate the Portfolio Risk Score is to estimate the systematic and idiosyncratic risk of a security and portfolio. The volatility estimate is calculated from either the HBSA approach using Morningstar's Risk Model or an RBSA approach depending on the holdings coverage.

Volatility Estimate by Morningstar Risk Model

With at least 80% holdings weight coverage, the system uses the outputs from Morningstar's Risk Model to estimate the portfolio's systematic and idiosyncratic risk. Morningstar Risk Model identifies the systematic drivers of security returns, which are commonly referred as *factors*. These factors include style, sector, region, and currency for equities and duration, spread, and credit for fixed income. It then uses the relationship among these factors and securities' factor exposures to estimate the systematic risk of a portfolio. This relationship among factors is captured by the factor variance-covariance matrix,

and the Risk Model supports a variety of methods to forecast the comovement. For the purpose of generating risk scores, we use an empirically derived long-horizon sample variance-covariance matrix. In addition to factor premiums, the Risk Model also produces residual terms for individual security, which represents the returns not explained by the systematic factors. We model the factor comovement over a 20-year window and residual volatility over a three-month window.

Prior to estimating the portfolio risk, the portfolio and TAI factor exposures are scaled in such a way that the missing holdings are assumed to have the same level of risk as the covered holdings in the portfolio. This is a more conservative way to estimate the overall portfolio risk because, if the exposures of the missing holdings are assumed zero (essentially equivalent to cash), it will underestimate the overall risk of the portfolio.

A portfolio's variance at time t , V_t^P , is modeled as:

$$(\sigma_s^P)^2 = (\vec{x}_t^P)^T \mathbf{F}_t \vec{x}_t^P \quad (\text{H-1})$$

$$(\sigma_u^P)^2 = (\vec{w}_t^P)^T \Delta_t \vec{w}_t^P \quad (\text{H-2})$$

$$V_t^P = (\sigma_s^P)^2 + (\sigma_u^P)^2 \quad (\text{H-3})$$

where

$\vec{x}_t^P$	= the m-element vector of the portfolio's exposures to the m Risk Model factors
$\vec{w}_t^P$	= the n-element vector of the portfolio's holdings weights where n is the number of securities in the portfolio
$\mathbf{F}_t$	= the m x m factor premium covariance matrix estimate
Δ_t	= the n x n diagonal matrix with residual variance estimates along its diagonal.
σ_s^P	= the systematic risk
σ_u^P	= the idiosyncratic risk

Volatility Estimate by Return-Based Style Analysis

With insufficient holdings data covered by the Risk Model, the system uses a returns-based-style analysis approach to estimate a security, fund, or portfolio's asset allocation. If the portfolio is a single security or fund, the system will analyze the time series of returns of the security or fund. For portfolios with multiple securities or funds, a custom time series of returns is constructed based on the current holdings and weights. Either way that it is determined, the time series of returns is analyzed using returns-based-style analysis as put forth in Sharpe [1988, 1992].

Sharpe's returns-based-style analysis, a specialized multifactor model, enables investors to determine a portfolio's effective asset mix using nothing more than historical returns and the historical returns of a broad set of asset-class indexes. The method described by Sharpe is a powerful and popular tool for determining the behavior (investment style) of portfolios and evaluating their performance. More formally, returns-based-style analysis takes the form:

$$r_{p,t} = x_1 a_{1,t} + x_2 a_{2,t} + \cdots + x_K a_{K,t} + e_t \quad (\text{R-1})$$

Where

$r_{p,t}$ is the return of the portfolio for $t = 1, 2, \dots, T$; T being the number of months, which is usually 48;
 $c_1, \dots, c_K$ are the asset-class coefficients for $k = 1, 2, \dots, K$; K being the number of asset-class indexes;
 $a_{1,t}, \dots, a_{K,t}$ are the period t returns for the K asset-class indexes; and
 e_t is the excess return at time t (for example, the portion of the return that is not explained by the returns of the K asset classes).

Returns-based-style analysis determines the asset-class coefficients ($x_1, \dots, x_K$) that minimize the variance of the excess return series (e_t), typically subject to $x_k \geq 0$ for $k = 1, 2, \dots, K$, and $x_1 + x_2, \dots, x_K = 1$. In other words, the values of the individual coefficients, or exposures, to the K asset classes are equal to or greater than 0 and sum to 1. These asset-class exposures form what is referred to as the *effective asset allocation* of the portfolio.

We use the returns-based style analysis results to form a custom benchmark for the portfolio. The returns on this benchmark are given by:

$$r_{b,t} = x_1 a_{1,t} + x_2 a_{2,t} + \cdots + x_K a_{K,t} \quad (\text{R-2})$$

Where

$r_{b,t}$ is the return of the benchmark for $t = 1, 2, \dots, T$

We then regress the benchmark returns on the portfolio returns:

$$r_{p,t} = \alpha + \beta r_{b,t} + u_t \quad (\text{R-3})$$

Where u_t is the residual term of the regression.

We use three results from this regression in the calculation of the risk score:

1. β . We use the estimated beta coefficient in the calculation of the systematic risk of the portfolio (for well-diversified portfolios, beta is close to 1).
2. The standard error of the regression (estimate of the standard deviation of u), which we denote σ_u . This is our estimate of unsystematic/idiosyncratic risk.
3. R2. The goodness-of-fit measure. We use this to determine the degree of confidence in the returns-based style analysis model and to set a floor for the Portfolio Risk Score.

For portfolios and securities with insufficient holdings data, we use the effective asset mix or effective asset allocation of the portfolio from the returns-based style analysis. This is the K -element vector of weights on the asset-class indexes included in the returns-based style analysis, which we denote $\vec{x}_p$.

Within a given country/region, we use the longest possible common period of asset index returns to estimate the $K \times K$ covariance matrix of asset-class returns, which we denote $\mathbf{V}$. We calculate the systematic risk of the portfolio as follows:

$$\sigma_S = |\beta| \sqrt{\vec{x}_P' \mathbf{V} \vec{x}_P} \quad (\text{R-4})$$

β being the slope coefficient in equation R-3. We combine this systematic risk with the idiosyncratic risk to calculate the total risk that will ultimately be translated into the risk score.

Both the holdings-based and returns-based methodologies result in the same application of the risk score function, and thus the same overall risk score.

R²-Based Floor

Returns-based style analysis is only useful if the asset-class index returns sufficiently explain the returns on the portfolio. The goodness-of-fit, or R^2 , statistic from the post-returns-based style analysis regression in equation (R-3) measures how well a returns-based style analysis model works. The holdings-based model does not require the post-returns-based style analysis regression and has no floor value for the Portfolio Risk Score. The goodness-of-fit for the holdings-based model is essentially the holdings coverage, and it is addressed by the 80% threshold and the factor exposure scaling.

A low R^2 indicates that there are other factors in the portfolio at play besides the asset-class returns. Since the Portfolio Risk Score is based on asset-class exposures, a low R^2 indicates that risk score is not an appropriate way to assess the risk of the portfolio.

We use the R^2 from the post-returns-based style analysis regression to set a floor on the value of the Portfolio Risk Score. To report the Portfolio Risk Score, we require that it be at least $100(1 - M \times R^2)$, where M is a parameter that we currently set to 3.

If the asset mix of the portfolio came about through either: 1) holding-based analysis, or 2) by specifying the asset mix apart from any actual investments, R^2 can be taken to be 100%.

Morningstar Portfolio Risk Score

We define the volatility ranges that constitute each risk band by the five-year history of volatility estimates of TAls. Exhibits 8 and 9 in Appendix A present the volatility profiles and percentiles of seven TAls that provide anchor points that are stable and do not overlap with each other over time. Through the series of empirical analysis of volatility distributions, we have determined that the median values of Moderate Conservative and Moderate Aggressive TAls can serve as the breakpoints among Conservative, Moderate, and Aggressive risk bands. For Very Aggressive and Extreme risk bands, we use maximum values of Aggressive Extension 1 and Aggressive Extension 2 TAls.

Exhibit 4 provides definitions for the risk bands in terms of volatilities and risk scores. The risk scores are in proportion to volatility ranges, with 28.2% volatility being a score of 100.

Exhibit 4 Mapping Between the Portfolio Annual Volatility and the Risk Score

	Volatility Range	Risk Score Range
Conservative	0% - 6.8%	0 - 24
Moderate	6.8% - 13.4%	24 - 48
Aggressive	13.4% - 22.2%	48 - 79
Very Aggressive	22.2% - 28.2%	79 - 100
Extreme Risk	28.2% - 50%	100 - 200

Source: Morningstar.

Based on this volatility to risk score mapping in each risk band, we rank portfolios by volatility. Because ranking such as percentile ranking is unstable when the market environment shifts dramatically or securities are removed from or added to the investment universe, we construct a grid that is fixed for a year. This risk score grid is tested monthly and updated with new data annually.

The procedure for constructing a risk score grid is straight-forward. For each risk band, we construct 10,000 equally spaced points that connect volatilities to risk scores. Here are some sample points on the grid to demonstrate the calculation.

For the 5,000th point in the Conservative risk band,

$$\text{Volatility} = \frac{5000}{10000} \times (6.8\% - 0\%)$$

$$\text{Risk Score} = \frac{5000}{10000} \times (24 - 0)$$

For the 15,000th point in the Moderate risk band,

$$\text{Volatility} = 6.8\% + \frac{15000 - 10000}{10000} \times (13.4\% - 6.8\%)$$

$$\text{Risk Score} = 24 + \frac{15000 - 10000}{10000} \times (48 - 24)$$

Beyond the 50,000th point in the Extreme risk band, we simply extrapolate points from any two points in the Extreme risk band. The risk band beyond the Extreme risk band cannot be reliably predefined because the maximum volatility is unknown until the universe is observed. The risk scores beyond 200 are capped at 500. Using two points in the Extreme risk band (v_1 , v_2 , rs_1 , rs_2), and the portfolio volatility v_p ,

$$\text{Risk Score} = rs_1 + (rs_2 - rs_1) \times \frac{v_p - v_1}{v_2 - v_1}$$

Conclusion

Financial professionals and those who oversee groups of financial professionals have a duty to make sure the portfolios they are using are well-diversified and that they are assigning individuals to an appropriate risk-based portfolio. With the creation of the volatility-based Morningstar Portfolio Risk Score, there is an objective and rigorous way for financial professionals (and individuals) to clearly understand how the portfolio risk was measured and run the risk assessment of nontraditional portfolio constructions that was otherwise challenging in the asset-allocation approach.

This system enables investors, financial professionals, compliance personnel, and regulators to assess risk (using a risk score) relative to the long-term risk profiles of Asset Allocation Indexes, in which the indexes have been used to create an intuitive risk spectrum. The system recalibrates the risk score grid to reflect changing volatility levels in the overall market. Because the risk score engine is powered by the Morningstar Risk Model, it can be further enhanced by the full capabilities of the holdings-based style analysis such as factor decomposition and in-depth analysis of risk attribution.

The Morningstar Portfolio Risk Score enables investors to be matched with portfolios that align with their risk profile as well as measure the risk of concentrated portfolios. There is an objective score published and calculated by Morningstar, plus there is the ability to frame the risk decomposition based on company-specific benchmarks. ■■■

Appendix A: Data

The volatility estimates presented here are from Morningstar Risk Model's HBSA methodology, and the time horizon is one year as of Nov. 30, 2022. The time windows for the forecast calculation are 20 years for the factor covariance matrix and three months for residual variance. The historical returns were used to calculate the realized volatilities in Exhibit 7.
